Introduction

Unfavorable moisture in seedbeds is a frequent cause of poor and unsynchronized seedling emergence (Angadi and Entz, 2002). On the other hand, achieving rapid and uniform seedling emergence is a key point for crop performance since slow germination rates frequently expose plantlets to adverse environmental conditions and soil-borne diseases (Osburn and Schraft 1989). Several authors (Patane et al. 2009; Ton et al., 2009; Paparella et al., 2015; Bosco de Oliveira and Gomes-Filho, 2016) have reported that seed priming treatments (pre-treatments) could accelerate germination and seed emergence, produce more vigorous plants, particularly under abiotic stress. Common bean (Phaseolus vulgaris L.) is one of the most important grain legumes for direct human consumption (Broughton et al., 2003), and although it is known to be susceptible to drought stress, common bean is frequently produced under water limiting conditions (Leport et al., 2006). Croatia has long tradition of common bean production which is based on landraces and usually takes place under rain fed conditions on small-scale farms (Carović-Stanko et al., 2017). Morphological and physiological traits, such as reduction of the leaf area, gas exchange adjustments, the distribution and conductance of stomata on the leaves, root system architecture, osmotic adjustment, and different phenoology represent adaptation mechanisms to drought stress in common bean (Beebe et al., 2007; Beebe et al., 2010; Rosales et al. 2012; Lanna et al. 2016; Polania et al. 2016). However, there is no single morphological or physiological trait which could be addressed to drought tolerance (Aruda et al., 2018).

Aim

The aim of this study was to investigate mitigating potential of hydro- and osmopriming to water deficit stress in seedlings of main Croatian common bean landraces.

Materials and methods

- Description of seed priming treatments is given in Table 1.
- After priming treatments, seeds were grown for 15 days in growth chamber, in pouches (Figure 1) dipped in ‘Magnavaca’ nutrient solution (Magnavaca et al., 1987).
- Conditions were: 75% air humidity of 25/20°C day/night temperature, and 18/6 h day/dark photoperiod (300 µmol m² s⁻¹ PAR).
- Seed germination and subsequent seed growth was performed under control conditions (0 MPa) and water deficit conditions (-0.3 MPa) applied by adding PEG 6000 to the nutrient solution.

Measurements

- Germination - number of germinated seeds was counted 9th day of the experiment (ISTA 1995).
- Root morphological traits (root length (RL), depth (RD), width (RW), surface area (RSA), volume (RV), average diameter (RAD), number of tips (RNT), number of forks (RFN)).
- Leaf chlorophyll content index (CCI).
- Gas exchange parameters (net photosynthesis rate (A), stomatal conductance (gₛ), transpiration rate (E), mesophyll CO₂ concentration (Ci), water use efficiency (WUE)).
- Chlorophyll fluorescence (Fv/Fm and Fv/Fo).
- Root fresh weight (RFW), shoot fresh weight (SWF), root dry weight (RDW) and shoot dry weight (SDW).
- Data were analysed using mixed model ANOVA. By combining water deficit treatments and priming treatments different groups were created and discriminant analysis (PROC DISCRIM) was performed to evaluate how valid the groups are, and which variables distinguish the best among them.

Results

- Water deficit decreased all measured root traits except average root diameter which increased.
- Water deficit increased average CCI, probably due to reduced SWF and SDW, but decreased average A and gₛ values.
- Irrespective to water deficit treatments, priming affected CCI (highest found in KNO₃ primed plants), and root traits (smallest values, except RAD, were found in PEG primed plants and the highest in CaCl₂ primed plants).
- The first axis of canonical correspondence analysis explains more than 50% of the total variation and differentiates among drought treatment and control treatment groups.
- First axis is positively correlated to root traits (except the RAD which is negatively correlated) and negatively to CCI.
- Second canonical component explains more than 20% of the total variation and differentiates among drought H₂O₂, drought CaCl₂ and control H₂O from other groups and is more correlated to gas exchange parameters.
